Image Segmentation

Dr. G.Karthick Associate Professor Department of ECE Jyothishmathi Institute of Technology & Science

Introduction to image segmentation

- The purpose of image segmentation is to partition an image into *meaningful* regions with respect to a particular application
- The segmentation is based on measurements taken from the image and might be *greylevel*, *colour*, *texture*, *depth* or *motion*

Introduction to image

segmentation

- Usually image segmentation is an initial and vital step in a series of processes aimed at overall image understanding
- Applications of image segmentation include
 - Identifying objects in a scene for object-based measurements such as size and shape
 - Identifying objects in a moving scene for *object-based* video compression (MPEG₄)
 - Identifying objects which are at different distances from a sensor using depth measurements from a laser range finder enabling path planning for a mobile robots
 - <u>Intro Video</u>

Introduction to image

segmentation

- Example 1
 - Segmentation based on greyscale
 - Very simple 'model' of greyscale leads to inaccuracies in object labelling

Introduction to image segmentation

- Example 2
 - Segmentation based on texture
 - Enables object surfaces with varying patterns of grey to be segmented

Introduction to image segmentation

6

Introduction to image

segmentation

- Example 3
 - Segmentation based on motion
 - The main difficulty of motion segmentation is that an intermediate step is required to (either implicitly or explicitly) estimate an *optical flow field*
 - The segmentation must be based on this estimate and not, in general, the true flow

Introduction to image segmentation

Introduction to image

segmentation

- Example 4
 - Segmentation based on depth
 - This example shows a range image, obtained with a laser range finder
 - A segmentation based on the range (the object distance from the sensor) is useful in guiding mobile robots

Introduction to image segmentation

Original image

Range image

Segmented image

- We will look at two very simple image segmentation techniques that are based on the greylevel histogram of an image
 - Thresholding
 - Clustering
- We will use a very simple object-background test image
 - We will consider a zero, low and high noise image

Noise free

Low noise

High noise

- How do we characterise low noise and high noise?
- We can consider the histograms of our images
 - For the noise free image, its simply two spikes at *i*=100, *i*=150
 - For the low noise image, there are two clear peaks centred on *i*=100, *i*=150
 - For the high noise image, there is a single peak two greylevel populations corresponding to object and background have merged

 We can define the input image signal-to-noise ratio in terms of the mean greylevel value of the object pixels and background pixels and the additive noise standard deviation

$$S / N = \frac{\left|\mu_b - \mu_o\right|}{\sigma}$$

Greylevel histogram-based

segmentation

- For our test images :
 - *S*/*N* (noise free) = ∞
 - *S*/*N* (low noise) = 5
 - *S*/*N* (high noise) = 2

- We can easily understand segmentation based on thresholding by looking at the histogram of the low noise object/background image
 - There is a clear 'valley' between to two peaks

- We can define the greylevel thresholding algorithm as follows:
 - If the greylevel of pixel p <=T then pixel p is an object pixel

else

• Pixel p is a background pixel

- This simple threshold test begs the obvious question how do we determine the threshold ?
- Many approaches possible
 - Interactive threshold
 - Adaptive threshold
 - Minimisation method

- We will consider in detail a minimisation method for determining the threshold
 - Minimisation of the *within group variance*
 - Robot Vision, Haralick & Shapiro, volume 1, page 20

Idealized object/background image histogram

22

- Any threshold separates the histogram into 2 groups with each group having its own statistics (mean, variance)
- The homogeneity of each group is measured by the *within group variance*
- The optimum threshold is that threshold which minimizes the within group variance thus maximizing the homogeneity of each group

- Let group o (object) be those pixels with greylevel <=*T*
- Let group b (background) be those pixels with greylevel >T
- The prior probability of group o is $p_o(T)$
- The prior probability of group b is $p_b(T)$

 The following expressions can easily be derived for prior probabilities of object and background

$$p_o(T) = \sum_{i=0}^{T} P(i)$$
$$p_b(T) = \sum_{i=T+1}^{255} P(i)$$
$$P(i) = h(i) / N$$

• where *h*(*i*) is the histogram of an N pixel image

• The mean and variance of each group are as follows :

$$\mu_{o}(T) = \sum_{i=0}^{T} iP(i) / p_{o}(T)$$

$$\mu_{b}(T) = \sum_{i=T+1}^{255} iP(i) / p_{b}(T)$$

$$\sigma_{o}^{2}(T) = \sum_{i=0}^{T} \left[i - \mu_{o}(T) \right]^{2} P(i) / p_{o}(T)$$

$$\sigma_{b}^{2}(T) = \sum_{i=T+1}^{255} \left[i - \mu_{b}(T) \right]^{2} P(i) / p_{b}(T)$$

• The within group variance is defined as :

$$\sigma_W^2(T) = \sigma_o^2(T)p_o(T) + \sigma_b^2(T)p_b(T)$$

- We determine the optimum *T* by minimizing this expression with respect to *T*
 - Only requires 256 comparisons for and 8-bit greylevel image

- We can examine the performance of this algorithm on our low and high noise image
 - For the low noise case, it gives an optimum threshold of T=124
 - Almost exactly halfway between the object and background peaks
 - We can apply this optimum threshold to both the low and high noise images

Low noise image

Thresholded at T=124

Low noise image

Thresholded at T=124

- High level of pixel miss-classification noticeable
- This is typical performance for thresholding
 - The extent of pixel miss-classification is determined by the overlap between object and background histograms.

- Easy to see that, in both cases, for any value of the threshold, object pixels will be miss-classified as background and vice versa
- For greater histogram overlap, the pixel missclassification is obviously greater
 - We could even quantify the probability of error in terms of the mean and standard deviations of the object and background histograms

Consider an idealized object/background histogram

36

- Clustering tries to separate the histogram into 2 groups
- Defined by two cluster centres c_1 and c_2
 - Greylevels classified according to the nearest cluster centre

- A *nearest neighbour* clustering algorithm allows us perform a greylevel segmentation using clustering
 - A simple case of a more general and widely used *K*-*means* clustering
 - A simple iterative algorithm which has known convergence properties

• Given a set of greylevels $\begin{cases} g(1), g(2), \dots, g(N) \\ \} \end{cases}$ • We can partition this set into two groups $\begin{cases} g_1(1), g_1(2), \dots, g_1(N_1) \\ \end{cases}$ $\begin{cases} g_2(1), g_2(2), \dots, g_2(N_2) \\ \end{cases}$

• Compute the local means of each group

$$c_1 = \frac{1}{N_1} \sum_{i=1}^{N_1} g_1(i)$$

$$c_2 = \frac{1}{N_2} \sum_{i=1}^{N_2} g_2(i)$$

Re-define the new groupings

$$\begin{aligned} |g_1(k) - c_1| < |g_1(k) - c_2| & k = 1..N_1 \\ |g_2(k) - c_2| < |g_2(k) - c_1| & k = 1..N_2 \end{aligned}$$

 In other words all grey levels in set 1 are nearer to cluster centre c₁ and all grey levels in set 2 are nearer to cluster centre c₂

- But, we have a *chicken and egg* situation
 - The problem with the above definition is that each group mean is defined in terms of the partitions and vice versa
 - The solution is to define an iterative algorithm and worry about the convergence of the algorithm later

• The iterative algorithm is as follows

Initialize the label of each pixel randomly

Repeat

 c_1 = mean of pixels assigned to object label c_2 = mean of pixels assigned to background label

Compute partition $\{g_1(1), g_1(2), \dots, g_1(N_1)\}$ Compute partition $\{g_2(1), g_2(2), \dots, g_2(N_2)\}$

Until none pixel labelling changes

- Two questions to answer
 - Does this algorithm converge?
 - If so, to what does it converge?
- We can show that the algorithm is guaranteed to converge and also that it converges to a sensible result

Outline proof of algorithm convergence
Define a 'cost function' at iteration r

$$E^{(r)} = \frac{1}{N_1} \sum_{i=1}^{N_1} \left(g_1^{(r)}(i) - c_1^{(r-1)} \right)^2 + \frac{1}{N_2} \sum_{i=1}^{N_2} \left(g_2^{(r)}(i) - c_2^{(r-1)} \right)^2$$

= $E^{(r)} > 0$

Now update the cluster centres

$$c_1^{(r)} = \frac{1}{N_1} \sum_{i=1}^{N_1} g_1^{(r)}(i)$$
$$c_2^{(r)} = \frac{1}{N_2} \sum_{i=1}^{N_1} g_2^{(r)}(i)$$

• Finally update the cost function

$$E_1^{(r)} = \frac{1}{N_1} \sum_{i=1}^{N_1} \left(g_1^{(r)}(i) - c_1^{(r)} \right)^2 + \frac{1}{N_2} \sum_{i=1}^{N_2} \left(g_2^{(r)}(i) - c_2^{(r)} \right)^2$$

Easy to show that

$$E^{(r+1)} < E_1^{(r)} < E^{(r)}$$

- Since *E*^(*r*) >0, we conclude that the algorithm must converge
 - but
- What does the algorithm converge to?

- *E*₁ is simply the sum of the variances within each cluster which is minimised at convergence
 - Gives sensible results for well separated clusters
 - Similar performance to thresholding

Conclusion

- We have seen several examples of grey level and colour segmentation methods
 - Thresholding
 - Clustering
